DEFORMATION OF CRACKED NET-REINFORCED CONCRETE WALLS

By Zdeněk P. Bažant, F. ASCE and Byung H. Oh

ABSTRACT: The deformation and crack width in concrete walls of slabs, plates, panels, and shells reinforced by a regular rectangular net of steel bars and subjected to in-plane (membrane) internal forces is analyzed taking into account the frictional-dilatant behavior of rough interlocked cracks, and for the dowel action of bars at crack crossings. The tension-stiffening effect, i.e., the restraint of the bars between the cracks due to their embedment in concrete, is also taken into account. Numerical computer studies are carried out. Reinforcement designs obtained from equilibrium conditions alone on the basis of either the classical frictionless approach or the recent frictional (slip-free) approach are compared in terms of the resulting crack widths. It is found that the use of frictional equilibrium design based on a low friction coefficient (0.75) leads to a much smaller crack width than the classical frictionless design when the reinforcement is laid in a direction which significantly deviates from the principal internal force direction. The influences of bar diameter and crack spacing on the crack width are also determined. The deformation analysis in which the frictional dilatant behavior of cracks, the dowel action, and tension stiffening are neglected leads to rather different values for the crack width.

INTRODUCTION

This paper analyzes the in-plane deformation of walls of concrete slabs, plates, panels, or shells that are intersected by a system of parallel continuous cracks. The walls are considered reinforced by a regular net of reinforcing bars, and are subjected to given in-plane (membrane) internal forces.

The reinforcement of such walls is in practice usually designed on the basis of equilibrium conditions alone, and no conditions on the deformations are used, partly because a realistic calculation of deformations is much more difficult. When all reinforcement is laid in directions that deviate from the principal directions of given internal forces by more than about 10°, the usual design method leads, however, to unacceptably large cracks, as often seen in structures. Some modification of the equilibrium design method, which retains its simplicity yet gives a smaller crack width in the case of a skew placement of reinforcement, therefore, is desirable.

The recently proposed frictional (slip-free) limit design of reinforcement is such a method. Like in the usual design, only equilibrium conditions are used. The results are identical to the classical, frictionless design when the bars are laid in the principal directions; but when they are laid skew the results are surprising. Equilibrium conditions indicate a heavier, and often much heavier, reinforcement when friction is considered than when it is not (3,5). In view of this fact we may expect the frictional design for skew reinforcement to lead to a smaller deformation than the frictionless design. This is what we need; but is the reduction of deformation sufficient? Can we avoid the complexity of a design based on deformation calculations if we use the frictional equilibrium conditions?

For walls reinforced by a regular net of bars, there seem to exist at present no precise test data from which to directly answer these questions. There does exist, however, numerous test data on the deformation due to cracks. A realistic incremental model (1) as well as a secant model (4) have recently been developed to reflect the experimentally observed behavior, chiefly the dilatancy of cracked concrete due to shear which is caused by a slip displacement on the cracks. Therefore, an attempt will be made here to calculate the deformations of the cracked reinforced wall on the basis of such a model. The secant slip-dilatancy model from Ref. 4, which is somewhat less realistic but easier to use and interpret than the incremental model (1), is chosen for this purpose. To determine the overall deformation of the wall, a simple method to take into account the tension-stiffening effect due to the bond between concrete and steel, particularly the restraining effect of the solid concrete between the cracks on the overall axial extension of the steel bars, and also the effect of the dowel action of the steel bars at crack crossings, will be developed.

The present problem has already been studied analytically by A. Gupta (11) and by A. Pitoňák (Visiting Scholar at Northwestern University—private communication). However, they neglected, for the sake of simplicity, the frictional-dilatant behavior of cracks and the effects of tension-stiffening and dowel action. Therefore, an effort is made here to extend these valuable pioneering studies by taking into account the aforementioned effects which, as will be seen, are quite significant, as already pointed out in a preceding discussion (2).

STATEMENT OF PROBLEM

Considered is a concrete wall reinforced by a regular net of reinforcing bars, and intersected by a system of parallel normal cracks at constant spacings. The bars, as well as the cracks, are assumed to be densely distributed. Although it would not be much more difficult to analyze skew nets or nets with bars in more than two directions, attention is limited to the rectangular nets (Fig. 1). The notations are: (1) x, y = cartesian coordinate axes oriented in the directions of bars, b1, b2 = spacings of bars of x and y directions; 0 = angle between the crack plane and axis y; (2) N1, N2 = given principal internal (membrane) forces in the wall, a = given angle between N1 and x; (3) 1py, 1py = steel reinforcement ratios.

The reinforcement must be designed so as to assure equilibrium for
FIG. 1.—Cracked Reinforced Concrete

FIG. 2.—Diagrams and Sketches for Cracked Reinforced Concrete
be equal the axial strain, $\varepsilon_{ax}$, in the bar. The strain outside the cone is considered zero.

Based on this crude simplification the strain energy (per bar) of the uniaxial stresses in both the steel and concrete between two adjacent cracks is

$$U = \frac{1}{2} E_s \varepsilon_s^2 A_s s' + \frac{1}{2} E_c \varepsilon_c^2 \left[ \frac{2\pi}{3k} \left( \frac{D + ks'}{2} \right)^3 - \frac{2\pi}{3k} \left( \frac{D}{2} \right)^3 - \pi \left( \frac{D}{2} \right)^2 s' \right]$$

(1)

in which $E_s$, $E_c$, $A_s = \pi D^2/4$; $D = \text{diameter of the bar}$; and $s' = \text{spacing of the cracks along the bars}$ = $s/cos \theta$ where $\theta = \text{angle between the bars and the normal to the crack planes}$ [Fig. 2(a)]. The slope of the diffusion cone may be taken as $k = 0.7$, although it would be better to calibrate $k$ according to test data. The strain energy in Eq. 1 must equal the strain energy $E_s \varepsilon_s^2 A_s s' / 2$ of the equivalent steel bar, and noting that $p_{eq}^2/p_s = A_s / A_s$, where $p = \text{actual steel ratio}$, and $p_{eq} = \text{equivalent steel ratio}$, this condition leads to

$$\frac{p_{eq}}{p} = 1 + \frac{ks'}{3D} \left( \frac{ks'}{D} + 3 \right)$$

(2)

Zero Bond Slip and Dense Bars.—If the bar spacing is too small, the cones of strained concrete considered in the first case overlap. Thus, the volume corresponding to one bar is less than that of the full cone [Fig. 2(e)]. Take the limiting cross section as a circle even though it is not; i.e., $A_s = \pi D^2/4$ or $D_2 = 2\sqrt{A_0}/\pi$, where $A_0 = \text{cross section area of the panel corresponding to one bar (and centrally symmetric with respect to the bar)}$; see Fig. 2(f). Eq. 1 may now be revised as follows:

$$U = \frac{1}{2} E_s \varepsilon_s^2 A_s s' + \frac{1}{2} E_c \varepsilon_c^2 \left[ \frac{\pi D^2}{4} \left( s' - 2D_2 - 3D_2 \right) - \frac{2\pi}{3k} \left( \frac{D}{2} \right)^3 - \frac{\pi D^2}{4} s' \right]$$

(3)

This must again equal $E_s \varepsilon_s^2 A_s s' / 2$ where $p_{eq} = A_s / A_s$, which yields

$$\frac{p_{eq}}{p} = 1 + \frac{Ec}{3ks'D^2 E_s} \left[ 3ks' \left( D_2^2 - D^2 \right) - D_2^2 \left( 2D_2 - 3D \right) - D^2 \right]$$

(4)

Bond Slip Limit.—If the axial strain, $\varepsilon_{ax}$, of the bar is too large, the bar would slip against concrete. The bond force per unit length of the bar is $U_{eq}$, as determined from pull-out tests. The axial force in the bar at the crack crossing is $\sigma_s A_s$. Due to the transfer of the load into concrete, the axial force in the bar decreases away from the crack [Fig. 2(c)]. Assuming this decrease to be linear (constant $U_{eq}$), the average axial force in the steel bar is $\sigma_s A_s - U_{eq} s'/4$. So the total extension of the bar between the cracks is $(\sigma_s A_s - U_{eq} s'/4) s'/(E_s A_s)$, which must equal the extension $\sigma_s A_s s' / (E_s A_s)$ of the equivalent bar. This yields

$$\frac{p_{eq}}{p} = \frac{1}{1 - \frac{U_{eq} s' \Delta \sigma_s}{4\sigma_s A_s}} \geq 1$$

(5)

Limit of Zero Steel Stress.—The preceding case can lead to a negative stress in steel if the spacing of cracks is too large. Thus we must impose the limit of zero steel stress at middistance between the cracks [Fig. 2(d)]. In this case the condition of equal extensions becomes $\sigma_s A_s s' / (E_s A_s) \geq \sigma_s A_s s' / (2E_s A_s)$, which yields

$$\frac{p_{eq}}{p} = 2$$

(6)

Among the four foregoing values, the minimum decides; i.e., the actual value is:

$$\frac{p_{eq}}{p} = \text{Min (Eqs. 2, 4, 5, 6)}$$

(7)

Stiffness Due to Dowel Action

The recent formulation of Walraven (25) is adopted here. His expression for the dowel force [Fig. 2(i)] is:

$$F_d = \frac{3\beta^2 E_s \beta_0}{3 + 6(\beta f)^2 + 2(\beta f)^3}$$

(8)

in which $\beta = (G_c D)^{1/4}$, $E_s = E_c \pi D^4 / 64$.

(9)

in which $G_c = \text{foundation modulus of concrete}$, $f = \text{free length of bar}$; and $\beta_0 = \text{reduction factor due to crack opening.}$ Tests of Elliott (6) and of Paulay, et al., (19) demonstrated that $G_c$ is independent of bar diameter, $D$, and led to the empirical expression

$$G_c = 34 \sqrt{f}; \beta_0 = 0.85$$

(10)

in which $f' = \text{cylinder compression strength (N/mm}^2\text{)}$ and $\beta_0 = \text{tangential relative displacement on the crack (in millimeters).}$ Furthermore, Elliott's tests (6) indicated that

$$\beta_0 = \frac{0.2}{\delta_n + 0.2}$$

(11)

in which $\delta_n = \text{normal relative displacement on the crack (in millimeters).}$

As for the free length, $f$, Schäfer (22) proposed, for the case of zero axial force in the bar, the free length $f = c, D$ tan $\theta$, in which $D = \text{bar diameter (in millimeters)}$ and $c$, = empirical constant (=1.0). The free length here reduces as $\theta$ decreases, which reflects the fact that for nonorthogonal cracks the dowel force causes a block of concrete in the acute angle to spall off [Fig. 2(g, i)]. The effect of the axial tensile force in the bar is to increase the free length, and according to Leonhardt's tests (15) the expression $f = c, D$ tan $\theta$ may be augmented as

$$f = c, D \tan \theta + \frac{\Delta \sigma_s}{45} D$$

(12)

in which $\Delta \sigma_s$, must be in N/mm$^2$. This represents the difference in steel
stress between the crack crossing and a remote location.

The dowel force is normal to the bar, and when the bar is inclined with respect to the crack, the dowel force, \( F_d \), is not parallel to the crack. The projections of \( F_d \) per unit cross section area in the normal and tangential directions of the crack plane as denoted are \( \sigma_m' \) and \( \sigma_m'' \), and then:

\[
\sigma_m' = \frac{F_d}{A_0} \sin \theta, \quad \sigma_m'' = \frac{F_d}{A_0} \cos \theta \tag{13}
\]

in which \( A_0 \) = the cross section area of the wall per bar.

**Stiffness of Cracked Reinforced Concrete**

To calculate the stiffness of cracked reinforced concrete, one may use a similar procedure as that in Ref. 4, but it must now be generalized to include the dowel action and the tension stiffening.

If the contribution of the axial forces in the bars is left for later separate consideration, the normal and shear stresses that are transmitted across the crack plane by the combined action of interlock of concrete surfaces [8,1,7,12,14,18,23,25] and the dowel (shear) forces in the steel bars may be expressed as \( \sigma_m' = \sigma_m'' \), \( \sigma_m = \sigma_m' + \sigma_m'' \), where \( \sigma_m' \) and \( \sigma_m'' \) are the normal and shear stresses transmitted through the crack plane by the action of concrete. (Without concrete, the bars can transmit their axial forces but not the dowel forces.) The frictional shear stresses, \( \sigma_m'' \), and the associated normal displacements are assumed to be governed (4) by the following friction law and the dilatancy law:

\[
\eta_m = \frac{-K\epsilon_m}{\tau_m \sin \phi} + c \frac{\phi}{\sin \phi} \quad \text{frictional slip}; \tag{14}
\]

\[
\delta_m = \gamma_m \epsilon_m \quad \text{dilatancy ratio}; \tag{15}
\]

in which \( k \) = friction coefficient; \( c \) = cohesion; \( \alpha_d \) = dilatancy ratio; and \( \epsilon \) = initial dilatancy.

From the macroscopic point of view, the effect of the relative displacements, \( \delta_m \) and \( \delta_t \), on many densely distributed parallel cracks of mean spacing, \( s \), is to produce the averaged strains

\[
\epsilon_m^{\prime} = \frac{\delta_m}{s}; \quad \epsilon_m^{\prime\prime} = 0; \quad \gamma_m^{\prime} = \frac{\delta_t}{s} \tag{16}
\]

in which \( \gamma_m^{\prime} \) = shear angle = \( 2\epsilon_m^{\prime\prime} \). The total strains of concrete containing many densely distributed parallel cracks may then be expressed as

\[
\epsilon = \epsilon^{\prime} + \epsilon^{\prime\prime} \tag{17}
\]

in which \( \epsilon^{\prime\prime} \) = column matrix \((\epsilon_m^{\prime\prime}, \epsilon_n^{\prime\prime}, \gamma_m^{\prime\prime})^T \); \( T \) denotes a transpose; and \( \epsilon \) and \( \epsilon^{\prime} \) are similar matrices representing the total strains and the strains in the concrete between the cracks. Assuming the concrete between the cracks to be isotropic and elastic, one may then write

\[
\epsilon^{\prime} = C_r \sigma^{\prime}; \quad C_r = \begin{bmatrix} E_c^{-1} & -\nu E_c^{-1} & 0 \\ -\nu E_c^{-1} & E_c^{-1} & 0 \\ \text{sym.} & -\nu E_c^{-1} & G_c^{-1} \end{bmatrix} \tag{18}
\]

in which \( \sigma^{\prime} = (\sigma_m^{\prime}, \sigma_n^{\prime}, \gamma_m^{\prime})^T \); \( C_r \) = the compliance matrix of uncracked concrete; and \( E_c, \nu \), and \( G_c \) are its Young's modulus, Poisson's ratio, and shear modulus, respectively. When the concrete is in a state of plane strain rather than plane stress, \( E_c \) and \( \nu \) must be replaced by \( E_c/(1 - \nu^2) \) and \( \nu/(1 - \nu) \), respectively. Note that \( E_c \) and \( G_c \) should be taken here as the secant moduli.

Substituting from Eqs. 16 and 17 \( \delta_m = s(\epsilon_m - \epsilon_m^{\prime}) \) and \( \delta_t = s(\gamma_m - \gamma_m^{\prime}) \) into Eq. 15, and expressing \( \epsilon_m^{\prime} \) and \( \gamma_m^{\prime} \) from Eq. 18, one obtains

\[
\epsilon_m - \frac{\sigma_m^{\prime}}{E_c} = \pm \alpha_d \left( \frac{\gamma_m^{\prime}}{G_c} + \frac{1}{s} \right) \tag{19}
\]

Noting that \( \epsilon_m^{\prime} = \epsilon_m^{\prime} \) and substituting \( \sigma_m^{\prime} = E_c \epsilon_m^{\prime} + \nu \sigma_n^{\prime} = E_c \epsilon_n^{\prime} + \nu(\sigma_n^{\prime} + \sigma_m^{\prime}) \) and \( \gamma_m^{\prime} = \mp k \sigma_m^{\prime} \pm c + \sigma_n^{\prime} \) into Eq. 19, one further obtains

\[
\frac{1 - \nu^2}{E_c} + \frac{1}{G_c} \left( \pm \alpha_d \right) (\pm \epsilon) \sigma_m^{\prime} = \epsilon_m + \nu \epsilon_n^{\prime} + \alpha_d \gamma_m^{\prime} + \frac{1}{G_c} (\pm \alpha_d) (\pm \epsilon) \tag{20}
\]

in which \( \pm \epsilon \) and \( \mp \gamma \) signs distinguish between slip to the right (top signs) and to the left (bottom signs). Expressing \( \sigma_m^{\prime} \) from Eq. 20 and substituting this into Eq. 14, one obtains \( \sigma_m^{\prime} \) and \( \sigma_n^{\prime} \). To get the total stresses of concrete alone, one must now make use of the equilibrium relations \( \epsilon_m^{\prime} = \epsilon_m^{\prime} + \nu \epsilon_n^{\prime} = E_c \epsilon_n^{\prime} + \nu(\sigma_n^{\prime} + \sigma_m^{\prime}) \). Noting that \( \sigma_n^{\prime} = E_c \epsilon_n^{\prime} + \nu \sigma_n^{\prime} = E_c \epsilon_n^{\prime} + \nu(\sigma_n^{\prime} + \sigma_m^{\prime}) \), it follows that

\[
\sigma^{\prime} = D^{\prime} \epsilon^{\prime} \tag{21}
\]

in which \( D^{\prime} = E^* \left[ \begin{array}{ccc} 1 & \nu & \mp \alpha_d \\ \nu & E_c^* + \nu^2 & \mp \alpha_d \nu \\ \mp k & \mp k \nu & (\pm \alpha_d)(\pm \epsilon) \end{array} \right] \)

\[
\epsilon = \frac{g_1 E^* + \sigma_m^{\prime} \mp \sigma_n^{\prime}}{\mp k \nu} \mp \alpha_d \nu (\pm \epsilon) \tag{22}
\]

\[
\mp k \nu = \frac{E_c}{G_c} (\pm \epsilon) \tag{23}
\]

\[
\frac{1}{E_c} + \frac{1}{G_c} (\pm \alpha_d)(\pm \epsilon) \tag{24}
\]

Matrix \( D^{\prime} \) represents the stiffness matrix of concrete that contains closely spaced parallel cracks whose surfaces slip and are in contact. The stiffness of reinforcement may now be brought into the picture. The total stress, \( \sigma^{\prime} = (\sigma_m, \sigma_n, \gamma_m)^T \), in the crack coordinates (n and t) may then be calculated as:
NUMERICAL STUDIES
AND ANALYSIS OF RESULTS

For the purpose of numerical calculations, the value \( N_1^P \) of the principal internal force due to the design loads is given. Let 0.75 \( N_1^P \) be due to the dead load, and 0.25 \( N_1^P \) to the live load. According to the ACI Code, the ultimate design must then be based on \( N_1 = 1.4 \) (0.75 \( N_1^P \)) + 1.7 (0.25 \( N_1^P \)) = 1.475 \( N_1^P \). The ratio \( m = N_1/N_1 \) and the angle, \( \alpha \), are also specified. The properties considered in numerical examples are \( E_c = 24,800 \text{ MN/m}^2; E_s = 200,000 \text{ MN/m}^2; \nu = 0.18; f_y' = 27.6 \text{ MN/m}^2; f_s = 276 \text{ MN/m}^2; \) bar spacing \( b = 15 \text{ cm}; N_1^P = 400 \text{ kN/m}; \) plate thickness \( h = 10 \text{ cm}; \) bar diameter \( D = 1.27 \text{ cm} \) (except where indicated differently); and capacity reduction factor \( \phi = 0.9 \). For ultimate bond force the formula \( U_b = 35\sqrt{f_y} \), with \( f_y \) in psi, is used. The crack spacing \( s \) is considered as 5 cm except where indicated differently. (In reality, of course, the crack spacing is also an unknown, depending on the steel ratio, bar diameter, type of concrete, and ultimate bond stress.)

A computer program has been written to calculate a great number of cases. For each case, the values of \( N_1, m(=N_2/N_1), \) and \( \alpha \) are assigned. On their basis the optimum reinforcement ratios \( p_x \) and \( p_y \) are determined using the formulas given in Refs. 3 and 5 (Appendix I). This is done for several values of the crack friction coefficient: \( k = 0.75, 1.7 \) (most realistic), \( k = \infty \). The last value of \( k \) gives results which are equivalent to the classical frictionless design of reinforcement (3.5).

After determining \( p_x \) and \( p_y \), the program calculates average membrane strains \((e_x, e_y, \gamma_y)\) of the reinforced wall, and the relative tangential and normal displacements on the cracks \( \delta_c \) and \( \delta_n \), \( (\delta_n \) is called the crack width even though the asperities may be in contact at nonzero \( \delta_n \)). The slip-dilatancy model, described in Ref. 4 and extended here, is used for this purpose.

The maximum crack width, \( \delta_{c,\text{max}} \), is found in the program by scanning the entire range of crack angle \( \theta \) for a given value of \( \alpha \). For each \( \alpha \) a series of discrete values of \( \theta \), increasing from 0°–180°, by steps of 1°, is selected. The crack width is then solved for each of them, and the case giving the maximum value is located among the results. For simplicity, the coefficients characterizing the cracks are assumed to be constant; also \( c = e = 0 \). For \( k \) and \( \alpha \) it seems appropriate to select the values that correspond to the load at which the cracks begin to slip and open significantly. According to tests, \( k \) is roughly 1.7 when the crack surfaces undergo a large slip (18). Moreover, the examination of the calculated response curves based on a theory that was calibrated by several test series (1) indicates also that \( k = 1.7 \) and \( \alpha = 1.0 \). Therefore, \( k = 1.7 \) and \( \alpha = 1.0 \) are selected as typical and most realistic values for the slip-dilatancy model.

The results of numerical studies are plotted in Figs. 4–7. Fig. 4 shows that consideration of tension-stiffening causes a significant reduction (from 12%–16%) in the resulting crack width, and that the additional consideration of dowel action causes a further appreciable reduction (about 9%). With regard to the effect of the angular deviation of reinforcement from the principal force direction, Fig. 5 shows the results when the tension-stiffening and the dowel action are both neglected (dashed lines) and when they are both taken into account. All this is shown for reinforcement designs obtained from equilibrium conditions alone on the basis of friction coefficients \( k = 0.75, 1.7, \) and \( \infty \). It is seen from the calculated plots that the use of \( k = 0.75 \) in the design, as compared to the frictionless design \((k = \infty)\), greatly offsets the increase of crack width due to angular deviation of reinforcement over the crack.
width for parallel reinforcement [in Fig. 5(d), it reduces a five-fold increase to a two-fold increase].

Fig. 6 shows again the effect of the angular deviation of reinforcement, now for the designs based only on $k = 1.7$ and, for different crack spacings and different bar diameters, the magnitude of which affects both the tension stiffening and the dowel action. It is seen that for a large crack spacing (100 mm or 4 in.) the influence of the bar diameter upon the crack width increase due to the angular deviation of reinforcement is much more intense than it is for a small crack spacing (25 mm or 1 in.).

Finally Fig. 7 shows the results obtained with the consideration of tension-stiffening and dowel action for different crack spacings and for dif-
Thus, the simple use of the frictional design allows a significant reduction to be carried out realistically (taking into account the aggregate interlock, quite important to consider these effects in calculations. The difference is significant (up to about 160%) when the bar direction deviates from the principal tensile force by more than about 5%, while of equilibrium conditions alone of either the classical frictionless approach or the recent frictional (slip-free) approach are compared in terms of the resulting crack widths for these different designs. The secant slip-dilatancy model is used.

The computer results lead to the following conclusions.

1. The tension stiffening effect reduces the calculated crack width by 10%–25%, and the dowel action further by as much as 10%. So, it is quite important to consider these effects in calculations.

2. The reinforcement designs obtained with different crack friction coefficients often lead to rather different crack widths for the same loads. The difference is significant (up to about 160%) when the bar direction deviates from the principal tensile force by more than about 5%, while for reinforcement that is laid in the direction of the principal tensile force no difference is obtained.

3. The use of friction coefficient \( k = 0.75 \) (which is lower than the realistic value of 1.7) in the equilibrium design of reinforcement assures that the crack width for any direction of reinforcement is no more than twice the crack width for parallel reinforcement. By contrast, for the frictionless design, for which \( k \rightarrow \infty \), the crack width for skew reinforcement may be as much as five-times larger than for parallel reinforcement. Thus, the simple use of the frictional design allows a significant reduction of the crack width for the cases of arbitrary skew reinforcement without the need of actually calculating the deformations and checking them against some limit. The crack width increase due to the angular deviation of reinforcement is somewhat less for larger crack spacings (80% vs. 50% increase for \( k = 1.7 \)) but is generally not strongly dependent on the assumed crack spacing (if the bar diameter is small; \( D = 12.7 \text{ mm or } 0.5 \text{ in.} \)).

4. The influence of bar diameter on the crack width increase due to angular deviation of reinforcement is for a large crack spacing stronger than it is for small crack spacing. For small diameters (\( \leq 0.5 \text{ in. ; 13 mm} \)), the influence of crack spacing is negligible, while for large diameters (1 in.; 25.4 mm) it is not.

5. The classical approach, in which the frictional dilatant behavior of cracks is neglected in the deformation analysis and the cracks are assumed to be oriented so that no slip displacement occurs on them (i.e., to be normal to the maximum principal strain direction), yields different values of the crack width.

**SUMMARY AND CONCLUSIONS**

The deformation and crack width of concrete walls reinforced by a regular rectangular net of reinforcing bars and subjected to in-plane (membrane) internal forces is analyzed on the basis of realistic models for the frictional dilatant behavior of rough interlocked cracks, and for the dowel action of bars at crack crossings. The tension stiffening effect, i.e., the restraining effect of the solid concrete between the cracks caused by bond stresses, is taken into account in terms of an equivalent steel ratio and is calculated by considering either slipping or nonslipping bars. The dowel action is modeled as an additional stiffness in the stress-displacement relation for the cracks. Extensive numerical computer studies have been conducted, and reinforcement designs obtained on the basis of equilibrium conditions alone of either the classical frictionless approach or the recent frictional (slip-free) approach are compared in terms of the resulting crack widths for these different designs. The secant slip-dilatancy model is used.

The computer results lead to the following conclusions.

1. The tension stiffening effect reduces the calculated crack width by 10%–25%, and the dowel action further by as much as 10%. So, it is quite important to consider these effects in calculations.

2. The reinforcement designs obtained with different crack friction coefficients often lead to rather different crack widths for the same loads. The difference is significant (up to about 160%) when the bar direction deviates from the principal tensile force by more than about 5%, while for reinforcement that is laid in the direction of the principal tensile force no difference is obtained.

3. The use of friction coefficient \( k = 0.75 \) (which is lower than the realistic value of 1.7) in the equilibrium design of reinforcement assures that the crack width for any direction of reinforcement is no more than twice the crack width for parallel reinforcement. By contrast, for the frictionless design, for which \( k \rightarrow \infty \), the crack width for skew reinforcement may be as much as five-times larger than for parallel reinforcement. Thus, the simple use of the frictional design allows a significant reduction of the crack width for the cases of arbitrary skew reinforcement without the need of actually calculating the deformations and checking them against some limit. This is a much more difficult task if it should be carried out realistically (taking into account the aggregate interlock, dowel action, and tension stiffening).

4. The influence of bar diameter on the crack width increase due to angular deviation of reinforcement is for a large crack spacing stronger than it is for small crack spacing. For small diameters (\( \leq 0.5 \text{ in. ; 13 mm} \)), the influence of crack spacing is negligible, while for large diameters (1 in.; 25.4 mm) it is not.

5. The classical approach, in which the frictional dilatant behavior of cracks is neglected in the deformation analysis and the cracks are assumed to be oriented so that no slip displacement occurs on them (i.e., to be normal to the maximum principal strain direction), yields different values of the crack width.

**ACKNOWLEDGMENT**

Financial support under National Science Foundation Grant No. CME8000450 to Northwestern University is gratefully acknowledged. Andrej Pitonak, Visiting Scholar at Northwestern University under the U.S.-Czechoslovakia Scientific Exchange Program, on leave from US-TARCO, Slovak Academy of Sciences, Bratislava, is thanked for carrying out certain valuable computer calculations which provided the stimulus for this work.

**APPENDIX I.—DESIGN OF OPTIMUM REINFORCEMENT**

A summary of the design procedure according to Refs. 3 and 5 will now be given. It will be also indicated how it should be adjusted to take into account the minimum reinforcement requirements. Let \( n_x = N_x/N_y \) and \( n_y = N_y/N_x \) in which \( N_x, N_y \) = principal internal forces \((N_y \geq N_x, N_x > 0)\), and \( N_x', N_y' \) = reinforcement yield forces. The safe design envelope is given by

\[
[(n_x - n_y^0) - \beta y (n_x - n_y^0)]((n_x - n_y^0) - \beta y (n_x - n_y^0)) = (2\beta y n_y^0)^2 \quad \cdots \cdots (28)
\]

in which \((n_y^0, n_x^0) = [1 + m \pm (1 - m) \cos 2\alpha]/2; \quad n_y^0 = (1 - m)(\sin 2\alpha)/2; \quad \beta y = 1/(1 + \sin \beta)\); and \( \beta y = (1 - \sin \beta) \beta. \) The optimum values are:

\[
(n_x)_{opt} = 1 + \frac{2}{(1 - m) \sin 2\alpha (\cosec \beta - \tan \alpha)} \quad \cdots \cdots (29)
\]

\[
(n_y)_{opt} = m + \frac{2}{(1 - m) \sin 2\alpha (\cosec \beta + \tan \alpha)} \quad \cdots \cdots (30)
\]

in which \( n = N_y/N_x \), \( \alpha \) is shown in Fig. 1; \( \beta = \arctan (k); \) and \( k \) = friction coefficient. Now, from Eqs. 29 and 30, the optimum reinforcement ratios are \( p_{x, opt} = \sigma_{x, opt} / \sigma_{y, opt} \), \( p_{y, opt} = \sigma_{y, opt} / \sigma_{x, opt} \) in which \( \sigma_{x, opt} = N_x/N_t \), \( h = \) wall thickness; \( \sigma_{x, opt} \) and \( \sigma_{y, opt} \) are axial stresses in the bars of directions \( x \) and \( y \) (\( \sigma_{x, opt} \) and \( \sigma_{y, opt} \) is taken as \( f_y \), in which \( f \) = capacity reduction factor; \( f_{y,y} = \) yield stress of bar). Assuming the dead-to-live load ratio 3:1, and introducing the respective load factors 1.4 and 1.7, leaves \( N_{x, opt} = 1.4 N_x + 1.7 N_y = 1.475 N_{y, opt} \). As already mentioned, one must use in Eqs. 28–30 the ultimate design value \( N_{y, opt} = 1.475 N_{y, opt} \) where \( N_{y, opt} \) is the design value of \( N_y \). Note that the safe design requires \( n_x \leq r_x = f_y p_x/\sigma_{x, opt} \) and \( n_y \leq r_y = f_y p_y/\sigma_{y, opt} \).
Some cases give a negative value for $n_{y,\text{opt}}$ or $n_{x,\text{opt}}$. This means that no tensile reinforcement is needed in the corresponding direction in this case. One must, however, use at least the minimum shrinkage and temperature reinforcement specified by section 7.12 of ACI Code (0.002 in case of a slab). The complete design procedure when either Eq. 29 or Eq. 30 gives a negative value is then as follows:

**Case 1.** If $n_{x} \leq 0$, set $p_{x} = p_{x,\text{min}}$ (given, e.g. 0.002), and $n_{x} = n_{x,\text{min}} = p_{x,\text{min}} \sigma_{x,\text{ult}}$. Then, if $n_{x,\text{min}} < r_{sp}$, solve Eq. 28 for $n_{y} = (n_{x})_{\text{opt}}$. If $n_{x,\text{min}} \geq r_{sp}$, substitute $n_{x} = (n_{x})_{\text{opt}} = r_{sp}$ in which [see Fig. 1(b) of Ref. 5]

$$r_{sp} = 1 + n_{y} \left[ \cos \beta + \sin \beta \sec \beta - \tan \alpha \right]$$

**Case 2.** If $n_{y} \leq 0$, set $p_{y} = p_{y,\text{min}}$ (given), and $n_{y} = n_{y,\text{min}} = p_{y,\text{min}} \sigma_{y,\text{ult}}$. Then, if $n_{y,\text{min}} < r_{Q}$, solve Eq. 28 for $n_{x} = (n_{y})_{\text{opt}}$ and if $n_{y,\text{min}} \geq r_{Q}$ substitute $n_{y} = (n_{y})_{\text{opt}} = r_{Q}$ in which [Fig. 1(b) of Ref. 5]

$$r_{Q} = 1 + n_{y} \left[ \cos \beta - \sec \beta - \tan \alpha \right]$$

$$r_{Q} = m + n_{y} \left[ \cos \beta + \sin \beta \sec \beta - \tan \alpha \right]$$
