Fracture Properties andBrittleness of High-Strength Concrete

by Ravindra Gettu, Zdeněk P. Bazant, and Martha E. Karr

The size-effect method for determining material fracture characteristics, as previously proposed by Bazant and extensively verified for normal strength concrete, is applied to typical high-strength concrete. Geometrically similar three-point bending specimens are tested and the measured peak load values are used to obtain the fracture energy, the fracture toughness, the effective length of the fracture process zone, and the effective critical crack-tip opening displacement. The brittleness of the material is shown to be objectively quantified through the size-effect method. Comparing the material fracture properties obtained with those of normal strength concrete shows that an increase of 160 percent in compressive strength causes: (1) an increase of fracture toughness by only about 25 percent, (2) a decrease of effective fracture process zone length by about 60 percent, and (3) more than doubling of the brittleness number, which may be an adverse feature that will need to be dealt with in design. The brittleness number, however, is still not high enough to permit the use of linear elastic fracture mechanics. The R-curves are demonstrated to derive according to the size-effect law exclusively from the maximum loads of specimens of various sizes and yield remarkably good predictions of the load-deflection curves.

Keywords: brittleness; cracking (fracturing); crack propagation; energy; fracture properties; high-strength concretes; load-deflection curve; models.

Concretes of strengths exceeding 80 MPa (12,000 psi) are now commonly being used in the construction of high-rise buildings and offshore structures.1-5 The utilization of concrete of such high strength has been spurred on by the superior mechanical properties of the material and its cost-effectiveness.6,7 The high-strength concrete of today is a highly engineered material with several chemical and mineral admixtures. It is possible to obtain workable mixes with very low water contents by using superplasticizers and retarders. Pozzolanic additives such as fly ash and silica fume are employed to alter the hydration reactions beneficially and also to fill the microscopic voids between cement particles. Small, round aggregates are used to achieve better mixing and attain higher surface areas for bonding. Typical high-strength concrete has a very high-strength matrix, is more compact, and possesses well-bonded aggregate-mortar interfaces.8

In the past, research on high-strength concrete has primarily concentrated on increasing its “strength.”9 In the last decade, however, considerable effort has been spent in studying its mechanical properties and structural behavior.1-6,7-12 Nevertheless, many aspects, such as fracture behavior, need much more detailed investigation.

A complicating feature in the fracture analysis of brittle heterogeneous materials such as concrete is nonlinear behavior. This is due to the fact that the fracture process is not concentrated at a point, the crack-tip, but is distributed over a zone whose size is not negligible when compared to the dimensions of the body. The existence of the large fracture process zone is manifested in the size effect exhibited by concrete specimens and structures, which is considerable but not as strong as in linear elastic fracture mechanics (LEFM). The conditions for which LEFM is applicable to concrete are attained only for extremely large test specimens, testing of which would be very costly. However, material fracture properties which are unambiguous and, especially, size- and shape-independent, can be defined only on the basis of a very large specimen or, more precisely, by means of extrapolation to a specimen of infinite size.

The simplest method to obtain size-independent material fracture properties is perhaps provided by extrapolating to infinite size on the basis of the size-effect law proposed in References 13 and 14 (see also Reference 15). This law approximately describes the transition from the strength criterion, for which there is no size effect, to LEFM criterion, for which the size effect is the strongest possible. This law has been shown to agree well with concrete fracture tests in Mode I,16 as well as Mode II17 and Mode III.18,19 A good agreement was also demonstrated for certain ceramics,20 rocks,21,22 and aluminum alloys.23

An important advantage of the size-effect method is its simplicity. The method requires only the maximum load values of geometrically similar specimens that are
The objectives will be to obtain the fracture energy and the process zone size. The third objective will be to investigate whether the R-curves derived solely from maximum load data yield load-displacement curves that agree sufficiently well with measurements.

REVIEW OF THE SIZE-EFFECT LAW AND ITS IMPLICATIONS

Size effect

Structures and test specimens of brittle heterogeneous materials, such as concrete, rock, and ceramics, exhibit a pronounced size effect on their failure loads. This phenomenon, which is an important consequence of fracture mechanics, has been described by the size-effect law proposed by References 13 and 14

\[
\sigma_c = \frac{Bf_0}{\sqrt{1+\beta}}, \quad \beta = \frac{d}{d_0}
\]

where \( P \) is the applied load, \( f(\alpha) \) is a geometry-dependent function of relative crack length \( \alpha = a/d \), \( a \) is crack length, \( g(\alpha) = [f(\alpha)]^2 \), \( E' = E \) for plane stress, \( E' = E/(1 - \nu^2) \) for plane strain, \( E = \) Young's modulus of elasticity, and \( \nu = \) Poisson's ratio. Values of \( f(\alpha) \) can be obtained by elastic analysis techniques, such as the finite element method, and for basic specimen geometries, formulas for function \( f(\alpha) \) can be found in fracture mechanics handbooks (e.g., Tada, Paris, and Irwin,25 and Murakami26).

When \( g'(\alpha) > 0 \) [where \( g'(\alpha) \) is the derivative of \( g(\alpha) \) with respect to \( \alpha \)], which applies to most situations, LEFM indicates that the maximum load occurs at infinitesimal crack extensions. Therefore, \( \alpha \) at maximum load is practically the same for bodies of different sizes. Setting \( G = G_f \) (fracture energy) or \( K_L = K_R \) (fracture toughness or critical stress intensity factor) along with \( P = P_b \), Eq. (2) according to LEFM yields the dependence of \( \sigma_c \) on size, which is \( \sigma_c = \text{constant}/\sqrt{d} \). As is well known, LEFM criteria govern only the fracture behavior of very large concrete structures.

In common-size concrete structures and specimens, the fracture process zone that forms in front of a propagating crack affects the behavior significantly. With increasing load, this zone grows in size while remaining attached to the notch tip [provided that the specimen geometry is such that \( g'(\alpha)>0 \)]. The process zone shields the propagating crack tip, and thereby increases the fracture resistance. The nonlinear fracture regime, where the influence of the process zone is dominant, lies between behavior governed by limit analysis and LEFM. As a result, there is a considerable size effect on the failure of normal concrete structures and specimens, but it is not as strong as that of LEFM. This transitional size effect is described by Eq. (1).

The size-effect law [Eq. (1)], giving the approximate relation of \( \sigma_c \) to \( \beta \) (the brittleness number), is plotted in Fig. 1. For large \( \beta \), such as \( \beta > 10 \), Eq. (1) gives (with an error under 5 percent) the approximation \( \sigma_c \propto d^{-\beta} \).
which is the size effect exhibited by LEFM. For small \( \beta \), such as \( \beta < 0.1 \), Eq. (1) yields (again with an error under 5 percent) \( \sigma_n = B f_e = \text{constant} \), that is, failure loads are proportional to the strength of the material and there is no size effect. For \( 0.1 < \beta < 10 \), the size effect is transitional between LEFM and plastic limit analysis. In this range, nonlinear fracture mechanics must be employed.\(^{16,24}\)

**Fracture parameters**

Nonlinear fracture can be characterized by two material parameters, the fracture energy \( G_f \) and the effective length of the fracture process zone \( c_f \). When determined from individual tests, however, these quantities are strongly size-dependent. Unambiguous definitions of \( G_f \) and \( c_f \) as fundamental material properties, independent of specimen size and shape,\(^{16,21,22,24}\) can be given on the basis of size effect: \( G_f \) and \( c_f \) are the energy required for crack growth and the effective (elastically equivalent) length of the fracture process zone, respectively, in an infinitely large specimen.

Mathematically, the definition of fracture energy can be stated as

\[
G_f = \frac{E' G}{E'} = \frac{K_I^2}{E'}
\]

where \( G \) and \( K_I \) are the apparent values of fracture energy and stress intensity factor, respectively, calculated according to LEFM [Eq. (2)] for the measured peak load \( P_u \) and initial crack or notch length \( a_o \).

Eq. (1) can be used to determine \( G_f \) and \( c_f \) from experimental data using their foregoing definitions. A simple formula for \( G_f \) has been derived in Reference 24

\[
G_f = \frac{B f_e}{c_f E'} d_o g(\alpha_o)
\]

For the effective length of the fracture process zone, the following expression has been derived in Reference 21

\[
c_f = \frac{d_o g(\alpha_o)}{g'(\alpha_o)}
\]

The ratio of \( c_f \) to the true length of the process zone in concrete depends on the shape of the softening stress-displacement or stress-strain relations. For concrete, the ratio\(^{19}\) seems to be about 2. However, the actual length of the process zone need not be known for the calculations.

Also, for an infinitely large specimen, the fracture toughness \( K_c \) can be obtained as

\[
K_c = \frac{E' G_f}{c_f} = \frac{B f_e}{d_o g(\alpha_o)}
\]

The practical applicability of Eq. (3) [or Eq. (5)] has been verified in Reference 16 through tests of normal concrete which showed that the three-point bend specimens, the double-notched tension specimens, and the eccentric compression specimens yield about the same value of \( G_f \). In this study we assume the same to be true of high-strength concrete.

Due to the approximate nature of Eq. (1), the infinite size used in the definitions of \( G_f \) and \( K_c \) must not be interpreted literally. In practice, the infinite size should be assumed as a size just beyond the upper bound of the range for which the size-effect law has been calibrated by tests or otherwise.\(^{24}\)

Using the relationships \( B = [E' G/g'(\alpha_o)c_f] c_f/\sigma_n \) and \( d_o = c_f g'(\alpha_o)/g(\alpha_o) \) in Eq. (1), the size-effect law can be reformulated in terms of the material fracture properties \( G_f \) and \( c_f \)

\[
\sigma_n = c_f \left[ \frac{E' G_f}{g'(\alpha_o)c_f + g(\alpha_o)d} \right]^{1/2}
\]

Alternatively, Eq. (6) can be put in a form convenient for the analysis of specimens which are not geometrically similar\(^{21}\)

\[
\tau_n = \left[ \frac{E' G_f}{c_f + \bar{d}} \right]^{1/2}
\]

where \( \tau_n = \sqrt{g'(\alpha_o) P_u/\bar{d}} \) and \( \bar{d} = d g(\alpha_o)/g'(\alpha_o) \); \( \tau_n \) is intrinsic (shape-independent) nominal stress at failure; and \( \bar{d} \) is intrinsic (shape-independent) size of the structure.

The brittleness number \( \beta \) [see Eq. (1)] proposed by Bazant can also be expressed as\(^{21,24}\)

\[
\beta = \frac{g(\alpha_o) d}{g'(\alpha_o)c_f} = \frac{\bar{d}}{c_f}
\]

This number is capable of characterizing the type of failure (brittle or ductile) regardless of structure geometry.\(^{18}\) It can quantify the proximity of the behavior of a structure to LEFM and therefore is a convenient and effective measure of the brittleness of a structure or specimen. It is also useful for comparing the behavior of specimens of different materials (with different compositions and strengths) such as high-strength and regular concretes. Other brittleness numbers defined for concrete by Hillerborg\(^{27}\) and Carpinteri\(^{28,29}\) can compare only structures of similar geometry.
The size-effect law in the form of Eq. (1), (6), or (7) has the advantage that its parameters $B$ and $d_0$, or $G_1$ and $c_r$, can be determined from the measured peak loads $P$ by linear regression.\cite{11,14} Eq. (1), applicable to geometrically similar specimens of different sizes, can be algebraically transformed to a linear plot

$$Y = AX + C$$

in which

$$X = d, \quad Y = (f_c/\sigma_N)^2, \quad B = 1/\sqrt{C} \quad \text{and} \quad d_0 = C/A$$

The size range of the specimens used in the regression analysis must be sufficiently large in relation to the random scatter of material properties and test measurements. For the typical scatter of concrete, the minimum size range recommended is 1:4.

The size-effect method can also be used to determine fracture properties other than those already defined. Considering the infinitely large specimen again, material parameters such as the effective (elastically equivalent) crack-tip opening displacement at the peak load, $\delta_{ct}$, can be related to $c_r$ and $K_{ic}$ using LEFM relations\cite{22}

$$\delta_{ct} = \frac{8K_{ic}}{E} \sqrt{\frac{c_r}{2\pi}}$$

The value of $\delta_{ct}$ pertains to the effective opening when the stress at the notch (or initial crack) tip is just reduced to zero, and the fracture process zone is about to detach and advance away from this tip.

The size of the fracture process zone can also be characterized by the length parameter

$$\ell_0 = \left(\frac{K_{ic}}{f_c}\right)^2$$

first used by Irwin\cite{30} for the size of the yielding zone in ductile fracture. For concrete, this length parameter was introduced by Hillerborg, Modéer, and Peterson.\cite{21} The parameter $\ell_0$ is a size-independent measure of the intensity of the toughening or crack-tip shielding mechanisms. It can be used to compare the brittleness of one material with another. A material with a relatively low $\ell_0$ would be more brittle than a material with a higher $\ell_0$.

**R-curves**

Another important consequence of the fracture process zone is the fracture resistance curve or R-curve. Since the fracture process zone evolves as it propagates, the resistance $R(c)$ to fracture growth, representing energy dissipated per unit length and width of fracture extension, gradually increases. The function $R(c)$, called the R-curve, was initially proposed to be used as a material property,\cite{32,33} independent of the shape of the specimen or structure. It was, however, shown\cite{34,35} that the R-curves for concrete strongly depend on the specimen geometry. A general derivation of the R-curve equations from the size-effect law as presented in Reference 21 yields the expression

$$R(c) = G_f \frac{g'(\gamma)}{g'(\alpha_0)} c$$

in which $\gamma$ is given by

$$c = g'(\alpha_0) \left[ \frac{g(\gamma)}{g'(\gamma)} - \gamma + \alpha_0 \right]$$

The foregoing relations [Eq. (13) and (14)] are valid as long as the fracture process zone remains attached to the tip of the initial crack or notch. This ceases to be true after the peak load.\cite{22} Since the fracture process zone in the post-peak regime is detached from the tip (separated from the initial tip by a traction-free crack) and is advancing ahead with approximately constant size, it dissipates roughly the same amount of energy per unit crack extension. Consequently, the critical value of $G$ after the peak load must be kept constant and equal to the values of $R$ reached at the peak load. The effective R-curves given by Eq. (13) and (14) are size-independent until the peak load but deviate afterwards into size-dependent horizontal branches. The size-dependence of R-curves in the post-peak regime has been previously observed for concrete\cite{36} and other materials.\cite{22,23,37} These effective R-curves tend to move toward complete coincidence with the actual R-curve as the size increases.\cite{22}

**EXPERIMENTAL INVESTIGATION**

**Test details**

High-strength concrete used in the construction industry varies widely in composition and strength. Even the demarcation between high and normal strength concretes is subjective and appears to be continually rising.\cite{24,26} To study typical high-strength concrete used in the industry, this investigation was conducted on material obtained directly from a batch mixed for the construction of a high-rise building in downtown Chicago.

The concrete mix was designed to exceed a 30-day compressive strength of 83 MPa (12,000 psi). Cement of much higher quality than standard (ASTM C 150) portland cement was selected. Silica fume (microsilica) and fly ash were used as mineral admixtures. The maximum aggregate size $d_a$ in the mix was 9.5 mm (3/8 in.). The details of the mix composition are given in Table 1. The proportions, by weight, of cement : sand : gravel : water : fly ash : microsilica were 1 : 1.35 : 2.42 : 0.35 : 0.25 : 0.04. The fresh concrete had a unit weight of 2410 kg/m$^3$ (151 lb/ft$^3$) and a slump of 235 mm (9.3 in.) as measured with a standard 305 mm (12 in.) cone.

Along with the fracture specimens, three 152 x 304 mm (6 x 12 in.) cylinders and three 102 x 204 mm (4 x 8 in.) cylinders were cast. These cylinders were capped with a sulfur compound and cured in a fog room.

Fig. 2 — Geometry of the three-point bending specimens used

Fig. 3 — Specimens of four different sizes

They were tested in compression after 14 days. The larger cylinders failed at an average maximum compressive stress of 85.5 MPa (12,400 psi), with a standard deviation of 1.4 percent. This value, denoted as $f'_{c14}$, was taken to be the mean compressive strength of the concrete. The smaller cylinders had an average compressive strength of 84 MPa (12,200 psi), with a standard deviation of 0.4 percent. The 28-day compressive strength of the concrete $f'_{c28}$, as measured by testing two $152 \times 304$ mm ($6 \times 12$ in.) cylinders, was 96 MPa (13,950 psi).

Beam specimens of four different sizes, three in each size, were cast from the same batch of concrete. All specimens were compacted by rodding and stored in the molds for 24 hr. They were then demolded and cured under water until the tests. The specimens (Fig. 2 and 3) were 38 mm (1.5 in.) thick and 305, 152, 76, and 38 mm (12, 6, 3, and 1.5 in.) deep. Their lengths were 8/3 times their depths and their spans 2.5 times the depths. Before testing, a notch 2 mm (0.08 in.) wide was cut at the midspan of each beam using a diamond band saw.

The length of the notch was one-third the depth of the beam.

The three-point bending test was used due to the relatively simple test setup and the impossibility of crack bifurcation. The peak loads of the largest specimens were measured by loading them under stroke control in a 534 kN (120 kip) load frame with an MTS control system. The other specimens were tested in a smaller load frame of 89 kN (20 kip) capacity, with a load cell operating in the 8.9 kN (2000 lb) range, and crack-mouth opening displacement (CMOD) control with an MTS closed-loop control system was used. A linear variable differential transformer (LVDT) with a range of 0.25 mm (0.01 in.) was mounted across the notch of each beam to monitor the CMOD. The measured CMOD was used as feedback to control the tests at a constant CMOD rate. This type of loading stabilized crack propagation even after the peak load and thus made it possible to obtain complete load-deflection curves for the specimens. The load-point displacements were measured between the tension faces of the beams and the cross-head of the loading ram with a 1.27 mm (0.05 in.) range LVDT. The load-displacement and load-CMOD curves were continuously recorded for each beam. The test setup is shown in Fig 4 and 5.
the beams were tested 14 days after casting and with CMOD rates such that they reached their peak loads in about 10 min. Typical curves for different specimen sizes are shown in Fig. 6 and 7, and the raw data are given in Table 2.

The test results from the largest beams were, however, excluded from the following analysis because their load values were inconsistent with the trend of the other tests. In retrospect, this inconsistency may be due to the difference in control parameters used for testing and in machine characteristics. Under stroke control, which was used only for the largest beams, it was not possible to obtain a stable response at the peak load. The instability of crack propagation may have caused a high crack propagation rate near the peak load. This might explain why the peak loads of these specimens were higher than expected.

The modulus of rupture of the material was used as the measure of its strength. Four specimens, each with a depth of 51 mm (2 in.) and a span of 152 mm (6 in.), were cut from two of the 152 mm (6 in.) deep fracture specimens that had already been tested. These unnotched beams were tested to failure in three-point bending under stroke control in the 89 kN (20 kip) load frame. From the peak loads the modulus of rupture of each specimen was calculated. The average value was found to be 11.0 MPa (1600 psi), with a standard deviation of 5 percent. Carrasquillo, Nilson, and Slate proposed an empirical formula for the modulus of rupture of high-strength concrete: 

\[
\frac{f_u}{\sqrt{d}} = 0.94 \sqrt{f_u} \text{ (stresses in MPa)}
\]

Using the value of \(f_u\) in their relation, \(f_u\) was obtained as 8.7 MPa (1260 psi). The difference in the values of \(f_u\) and \(f_u\) may partly be due to errors in the predictions of the formula (known to be up to 15 percent) but it might also be due to the significant size effect which is known to exist in flexural tests on plain concrete beams.

As noted previously by several researchers, cracks in high-strength concrete were seen to propagate through the coarse aggregates. This is an important difference from normal strength concrete, in which cracks (in the vicinity of gravel particles) propagate mainly along the aggregate-mortar interfaces. The reduced crack deflection by the aggregates is due to the strong aggregate-mortar bond and the fact that the strength of the matrix approaches that of the aggregates. Obviously, this near-homogeneous behavior decreases the width of the process zone as well as the shielding effect of the aggregates.

Analysis

Linear regression analysis (Fig. 8), using Eq. (9) and (10), yields coefficients \( A = 1.58 \text{ mm}^{-1} (40.1 \text{ in.}^{-1}) \) and \( C = 51.7 \). The coefficient of variation of the deviations from the regression line is \( \omega = s_{yx}/\bar{y} = 15 \text{ percent} \), where \( s_{yx} \) is the standard error of the \( Y \) estimate and \( \bar{y} \) is the mean of the experimental \( Y \)-values. From Eq. (10), the parameters of Eq. (1) are computed as \( B = 0.139 \) and \( d_0 = 32.8 \text{ mm} (1.29 \text{ in.}) \). Nonlinear regression analysis directly for \( B \) and \( d_0 \), using the Marquardt-Levenberg algorithm, results in \( B = 0.198 \) and \( d_0 = 13.3 \text{ mm} (0.52 \text{ in.}) \) with \( \omega = 8.4 \text{ percent} \). Since the nonlinear regression provides a better fit, the latter values for the size-effect parameters are used henceforth.

Fig. 9 shows the size-effect curve [Eq. (1)] based on the calculated parameters along with the experimental

values of normalized nominal stress. The trend of the data is fitted very well by the size-effect law. For comparison; data from similar tests of normal strength concrete (particulars given later) are also shown. It is now important to observe that the data points of the high-strength concrete beams lie closer to the LEFM criterion than those of usual concrete. This indicates that the same specimen made of high-strength concrete behaves in a more brittle manner than that made of regular concrete. Yet the behavior of the present specimens cannot be described by LEFM. For LEFM relations to apply with errors less than 2 percent, the brittleness number $\beta$ would have to be greater than 25, i.e., the beam depth would have to exceed 334 mm (13 in.).

For the specimen geometry used, the function $f(\alpha) = 6.647\sqrt{\alpha} \left(1 - 2.5\alpha + 4.49\alpha^2 - 3.98\alpha^3 + 1.33\alpha^4\right)/(1 - \alpha)^{0.5}$ was obtained by fitting the results of linear elastic finite element analysis. Using $g(\alpha) = 14.20$ and $g'(\alpha_0) = 72.71$ in Eq. (5), $K_e$ is 30.0 MPa$\sqrt{\text{mm}}$ (864 psi$\sqrt{\text{in.}}$), and the value of $c_f$ from Eq. (4) is 2.6 mm (0.10 in.). This yields $c_f = 0.3d_a$. From Eq. (12), $t_0$ for the concrete tested is 7.4 mm (0.29 in.), which is about 0.8$d_a$. Young’s modulus of elasticity $E$ may be computed from

$$Y = 1.58X + 51.7$$

$$f_u = 11.0 \text{ MPa}$$

Fig. 8 — Linear regression for size-effect parameters

![Image 1](image1.png)

$$f' = 0.62\sqrt{f_c} (\text{ACI}); f' = 0.50\sqrt{f_c} (\text{ACI}); E = 4735 \sqrt{f_c}; E = 6900 \text{ in MPa},$$

$$G_f = (2.72+3.103f'_c)f'_c; \delta_y = 4.11 \times 10^{-3} \text{ mm (1.60 \times 10^{-4} in.)}.$$  

For comparison, it is interesting to consider the results of similar tests on normal strength concrete with $d_a = 13 \text{ mm (0.5 in.)}$. The relative proportions of cement: sand : gravel : water, by weight, were 1 : 2 : 2 : 0.6. The specimens and loading setup were identical to the present ones except that the notch lengths were one-sixth of the beam depth. The curing conditions were the same as those of the high-strength specimens. The tests were conducted 28 days after casting and, therefore, the parameters corresponding to 14 days had to be estimated to this effect, and the following relations were used: $f_c = 32.5 \text{ MPa (4700 psi)}, f_c = 27.0 \text{ GPa (3.91 \times 10^6 psi)}, f_c = 3.5 \text{ MPa (510 psi)}, K_e = 24.0 \text{ MPa} \sqrt{\text{mm}} (690.1 \text{ psi} \sqrt{\text{in.}}), c_f = 6.6 mm (0.26 in.), G_f = 21.4 \text{ N/m (0.122 lb/in.)}, \delta_y = 7.29 \times 10^{-3} \text{ mm (2.87 \times 10^{-4} in.)}, \text{ and } t_0 = 46 \text{ mm (1.80 in.)}$. The values of $c_f$ and $t_0$ are about 0.5$d_a$ and 3.6$d_a$, respectively. A graphic comparison of the properties of the high-strength concrete and the regular concrete is presented in Fig. 10.

As concluded by recent investigators of high-strength concrete fracture, $G_f$ and $K_e$ increase with strength, but much less than does the material strength itself. For an increase in strength ($f'_c$) of about 160 percent, $G_f$ and $K_e$ increase only by 12 and 25 percent, respectively. More significantly, the values of $c_f$ and $t_0$, especially the latter, decrease considerably with increase in strength. This implies that the size of the process zone must be

ACI Materials Journal / November-December 1990
smaller in high-strength concrete than in regular concrete, and the crack-tip shielding by the fracture-process zone must be weaker. Consequently, the same structure made of high-strength concrete is more brittle than that made of regular concrete. The brittleness number of any structure is more than doubled, since it is inversely proportional to the value of $c$.

Conventional fracture analysis of the type applied to metals, based only on $K_{lc}$ or $G_f$, would yield the misleading conclusion that the ductility of concrete increases with strength, e.g., see De Larrard, Boulay, and Rossi. This was also pointed out by John and Shah on the basis of tests on high-strength mortar.

According to RILEM recommendations, the fracture energy, denoted as $G_f$, is defined by the work-of-fracture method introduced for ceramics by Nakayama and Tattersall and Tappin, and proposed for concrete by Hilerborg. In this method, $G_f$ can be determined from the area $W_o$ under the load-deflection curve of a fracture specimen. The total energy dissipated in the test is given by $W = W_o + mg u_o$, where $mg$ = weight of the specimen and $u_o$ = deflection when the beam fractures completely. The RILEM fracture energy is assumed to be the average dissipated energy per unit cracked surface area; therefore, $G_f = W / (d - a_o)b$, where $d = depth of the beam and $a_o$ = initial notch length. For practical reasons, $u_o$ was taken to be the deflection when load had dropped to 10 percent of the measured peak load. The corresponding fracture toughness can be obtained as $K_u = \sqrt{G_f / E_o}$, where $E_o$ is the Young’s modulus corresponding to the initial compliance. The values of $K_u / K_{lc}$ vary from the size-effect law [Eq. (14) and (15)], but after the peak load, as mentioned earlier, the R-curves can be obtained from Eq. (16) and (17), for different chosen values of $\alpha$ or $c$, yielding the load-deflection curve of the structure or specimen with a propagating crack. Before the peak load, one uses the R-curve values derived from the size-effect law [Eq. (14) and (15)], but after the peak load, as mentioned earlier, the R-curves, as well as $K_u(c)$, is constant.

To obtain the total deflections, the elastic deflections $u_b$ and $u_s$ due to bending and shear must also be calculated. Assuming plane stress conditions and adopting the bending theory, the load-point displacement $u_o$ of the beam without crack is

$$u_b = u_o + u_s$$

$$u_s = \frac{PL}{4bdE}$$

$$u_s = 0.6(1 + v) \frac{PL}{bdE}$$

where $L$ is the span of the specimen, and $u_b$ and $u_s$ are the contributions of bending and shear, respectively. The weight of the beam is approximately taken into account in the calculations by replacing it with a concentrated midspan load which produces an equivalent midspan moment.

Fig. 12(a) through (c) compare the predictions of the foregoing method for the present high-strength concrete beams with the measured load-deflection curves for specimens of three different sizes. The Young's
CONCLUSIONS

1. The size-effect method provides reliable fracture properties for high-strength concrete with a very simple experimental setup. These properties, namely, the fracture energy (or fracture toughness) and the effective length of the fracture process zone (as well as the effective critical crack-tip opening displacement derived from them) are size-independent and, therefore, true material properties.

2. As the strength increases, the fracture energy and the fracture toughness of concrete also increase, although much less than the strength. The effective size of the fracture process zone, however, diminishes. This results in decreased crack-tip shielding and, consequently, increase in the brittleness of specimen or structure. Increasing the compressive strength by 160 percent causes the brittleness number to more than double. This property can be disadvantageous and needs to be addressed in design.

3. Despite the aforementioned increase in brittleness, the behavior of contemporary high-strength concrete, in the normal size range, is still governed by nonlinear fracture mechanics rather than linear elastic fracture mechanics.

4. The R-curves derived according to the size-effect law solely from maximum loads can be utilized to provide reasonably accurate predictions of the load-deflection curves of concrete structures, even in the post-peak regime. The procedure requires only: (a) knowledge of the linear elastic fracture mechanics relations for the geometry of the structure and (b) the values of two basic material fracture parameters obtained from maximum loads through the size-effect method.

This work was partially supported by the Center for Advanced Cement-Based Materials at Northwestern University (NSF Grant DMR-8808432). The underlying basic theory was developed under partial support from AFOSR Contract 49620-87-C-0030DEF with Northwestern University. Summer support for M. E. Karr was provided under NSF Grant BCS-8818230. The authors are grateful to Jaime Moreno and Arthur King of Material Services Corporation, Chicago, Ill., for donating the concrete used in the experiments.

NOTATION

\( a \) = effective crack length  
\( b \) = specimen thickness  
\( c \) = elastically equivalent crack growth  
\( c_i \) = effective length of fracture-process zone  
\( c_i \) = coefficient for convenience (here, equal to 1)  
\( d \) = characteristic specimen dimension (here, specimen depth)  
\( d_i \) = maximum aggregate size  
\( d_i \) = parameter determined experimentally  
\( f'_{c} \) = 28-day compressive strength  
\( f_{c} \) = 14-day compressive strength  
\( f_{m} \) = some measure of material strength  
\( g(a) \) = function dependent on specimen shape  
\( g'(a) \) = derivative of \( g(a) \) with respect to \( a \)  
\( d_{p} \) = parameter related to the size of the process zone  
\( A \) = slope of linear regression plot  
\( B \) = parameter determined experimentally  
\( C \) = intercept of linear regression plot
